Abstract

We investigate the sensitivity of the Atlantic meridional overturning circulation to the vertical diffusion coefficient $\kappa$ in the global coupled atmosphere-ocean-sea-ice model CLIMBER-3$\alpha$. An important feature of the three-dimension ocean model is its low-diffusive tracer advection scheme. We decompose the strength $M_{\text{max}}$ of the Atlantic overturning into three components: (1) the flow $M_S$ exported southward at 30°S, (2) the large scale upward flow that balances vertical diffusion in the Atlantic, and (3) a wind-dependent upwelling flux $W_{\text{bound}}$ along the Atlantic boundaries that is not due to vertical diffusion.

The export of water at 30°S varies only weakly with $\kappa$, but is strongly correlated with the strength of the overflow over the Greenland-Scotland ridge. Location of deep convection is found to be mixing dependent such that a shift from the Nordic Seas to Irminger Sea is detected for high values of $\kappa$. The ratio $R = M_S/M_{\text{max}}$ gives a measure of the interhemispheric overturning efficiency and is found to decrease linearly with $\kappa$. The diffusion-induced upwelling in the Atlantic is mostly due to the uniform background value of $\kappa$ while parametrisation of enhanced mixing over rough topography and in stratified areas gives only a weak contribution to the overturning strength. It increases linearly with $\kappa$. This is consistent with the classic $2/3$ scaling law only when taking the linear variation of the density difference to $\kappa$ into account. $W_{\text{bound}}$ is roughly constant with $\kappa$.
but depends linearly on the wind stress strength in the North Atlantic. The pycnocline depth is not sensitive to changes in $\kappa$ in our model, and the results suggest that it is primarily set by forcing of the Southern Ocean winds.

The scaling of the total overturning strength with $\kappa$ depends on the combined sensitivity of each of the terms to $\kappa$. In the range of background diffusivity values where no switch in deep convection sites is detected, $M_{\text{max}}$ scales linearly with the vertical diffusivity. We argue that scalings have in general to be interpreted with care due to the generally very small range of $\kappa$ but also due to possible shifts in important physical processes such as deep convection location.
1 Introduction

The northward heat transport in the Atlantic is mainly assumed by the Atlantic meridional overturning circulation (AMOC), defined as the zonally integrated meridional transport in the Atlantic. It is at present of about $10^{15}$ W (Ganachaud and Wunsch 2000). Paleoreconstructions (McManus et al. 2004) and model studies (e.g. Ganopolski et al. 1998) suggest that this value, as well as the intensity and shape of the AMOC itself has significantly varied in the past (see reviews by Clarke et al. 2002 and Rahmstorf 2002). Yet, the mechanisms that control its shape and strength are still under debate. In this paper, we aim at better understanding how the interior vertical diffusivity influences the AMOC in a coupled ocean-atmosphere-sea-ice model.

Several recent studies suggest that the largest fraction of energy needed to explain the oceanic heat transport is provided by winds (e.g. Boccaletti et al. 2005, Gnanadesikan et al. 2005). Toggweiler and Samuels (1993, 1995) proposed that the entire Atlantic overturning be sustained by wind-driven upwelling occuring in the Southern Ocean. This is in contradiction with inversion studies that yield a picture of the AMOC including non-negligible tropical upwelling (e.g. Ganachaud and Wunsch 2000, Talley et al. 2003). Theoretical considerations and idealised model studies also rather point at the downward mixing of heat at low latitudes as limiting the rate of overturning in the sense of energy input (e.g. Munk and Wunsch 1998, Marotzke and Scott 1999, Huang 1999). Assuming
geostrophy and advective-diffusive buoyancy balance in the pycnocline, scaling arguments suggest that the maximum strength $\Psi$ of the meridional streamfunction in the North Atlantic, obeys

$$\Psi \sim \kappa^\alpha \Delta \rho^{1/3}, \quad \alpha = 2/3$$

(1)

where $\kappa$ is the vertical diffusion parameter and $\Delta \rho$ is the equator-to-pole density difference (Bryan and Cox 1967, Bryan 1987). Different exponents $\alpha$ have however been found in different idealized models (e.g. Colin de Verdière 1988, Hu 1996, Marotzke 1997, Zhang et al. 1999, review in Park and Bryan 2000). Using a 3-dimensional global ocean general circulation model (GCM), Prange et al. (2003) find a relatively good agreement with the $\alpha = 2/3$ scaling law when taking into account the effect of vertical mixing on the density difference, although their figures suggest relatively large error bars. To our knowledge, this is so far the only experiment that have been carried in global ocean model, in spite of the possible effect of the Southern Ocean (e.g. Gnanadesikan 1999) and of the Indian and Pacific basins.

The stability of the overturning in the presence of an anomalous freshwater flux at high latitudes is also a crucial issue in climate research. Simulations of future climate scenarios indeed predict that under increased greenhouse gas forcing, the freshwater flux into the North Atlantic ocean will increase as a result of an intensified hydrological cycle and melting of the cryosphere. Furthermore, abrupt climate changes in the past are
believed to have their origin in the response of the Atlantic MOC to an anomalous input of freshwater in the Atlantic (e.g. Rahmstorf 2002). The scaling analysis presented above, supported by modelling studies, imply that the sensitivity of the overturning to anomalous freshwater fluxes in high latitudes might be reduced in the presence of vertical mixing (e.g. Park 1999, Manabe and Stouffer 1999, Prange et al. 2003) since the initial weakening of the overturning would be counteracted by a deepening of the pycnocline. On the other hand, recent findings by Levermann and Griesel (2004) point out that one of the fundamental assumptions of this scaling, namely the scaling of the overturning strength to the pycnocline depth, is not necessarily valid.

The dynamics of the overturning circulation in a global coupled model finally remains poorly understood and its scaling behavior is largely untested. Here, we analyze the sensitivity of the Atlantic overturning to the vertical diffusivity in present-day conditions in a global coupled atmosphere-ocean-sea-ice model of intermediate complexity. This is the first study that addresses this issue in a coupled model without flux adjustment. Following ideas of Hasumi and Suginohara (1999) and measurements of Ledwell et al. (2000), the model includes a parametrisation of enhanced oceanic mixing over topography and dependent on the stratification of the water column. In addition, special care has been taken to minimize the numerical diffusivity by implementing a low-diffusive advection scheme. This point is crucial for our attempt to investigate the sensitivity to the mixing
coefficient. As a result, we propose a simple decomposition of the MOC into physical components that could be used as a framework for further sensitivity studies of the MOC to vertical mixing.

The paper is organised as follows: the model and the experiments are described in section 2, the sensitivity of the AMOC to vertical diffusivity in the model in section 3. In section 4, this sensitivity is discussed in more detail by decomposing the AMOC strength into three physical components: (1) outflow towards the Southern Ocean at 30°S, (2) diffusion-driven upwelling in the Atlantic, and (3) wind-dependent upwelling along the boundaries. Results are discussed and conclusions are given in section 5.

2 Model description and experimental set-up

The model used in this study is CLIMBER-3α, described by Montoya et al. (2005). It consists of the atmospheric model POTSDAM-2 (Petoukhov et al. 2000) coupled to a global, 24-layers ocean GCM based on the GFDL MOM-3 code and to the dynamic and thermodynamic sea-ice module of Fichefet and Maqueda (1997). The oceanic horizontal resolution is 3.75° × 3.75°. A second order-moment advection scheme (Prather 1986) was implemented for the tracers in order to minimize numerical diffusivity. This scheme is widely used in the atmospheric science community and is low-diffusive compared to traditional advection schemes such as FCT and QUICK (Hofmann and Maqueda in prep.).
The mixing explicitly imposed in the ocean model is thus the one effectively felt by the circulation. Our study is mainly based on the analysis of 10 experiments that differ only in the value of the background vertical diffusion coefficient $\kappa$, set successively to $\kappa = 0.05, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.75, 1$ and $1.5 \text{ cm}^2 \cdot \text{s}^{-1}$. In six additional experiments, $\kappa$ was kept fixed to the low value $\kappa = 0.1 \text{ cm}^2 \cdot \text{s}^{-1}$ poleward of $40^\circ$ and set respectively to $\kappa^{lowlat} = 0.3, 0.5, 0.6, 0.75, 1, 1.5 \text{ cm}^2 \cdot \text{s}^{-1}$ in the rest of the ocean. In addition to this background vertical diffusivity, all the runs include a parametrisation of boundary enhanced mixing, with vertical diffusivities depending both on near-bottom stratification and roughness of the topography, as suggested by Hasumi and Suginohara (1999) and by measurements of Ledwell et al. (2000) (see Montoya et al. 2005). The model uses furthermore the K-profile parametrisation (KPP) scheme introduced by Large et al. (1994). The effective mixing $\kappa^*$ felt by the ocean thus differs from the background value $\kappa$ primarily in the mixed layer and over rough topography. The difference between the two is less than 10% in the ocean interior (Fig. 1). No grid based horizontal diffusion is imposed, but an isopycnal diffusion with a coefficient of $\kappa_{iso} = 1000 \text{ m}^2 \cdot \text{s}^{-1}$ is applied. An eddy-induced tracer advection following Gent and McWilliams (1990) was implemented using the skew flux representation by Griffies (1998) with a thickness diffusion coefficient of $\kappa_{gm} = 250 \text{ m}^2 \cdot \text{s}^{-1}$. The sensitivity of the overturning to this parametrisation is investigated in a separate study by Griesel and Maqueda (2005). In order to focus on the effect of changes in
vertical mixing, the wind stress is prescribed from the NCEP-NCAR reanalysis (Kalnay et al. 1996). Note however that the wind velocity itself and the buoyancy fluxes do depend on the surface temperatures, in a very similar way as in classic coupled GCMs.

The POTSDAM-2 model is based on the assumption of a universal vertical structure of temperature and humidity, which allows reducing the three-dimensional description to a set of two-dimensional, vertically averaged prognostic equations for temperature and humidity but allows full coupling with the ocean surface. The reader is referred to Montoya et al. (2005) for an explicit description of the coupling. Additional experiments were performed with the same model to test the sensitivity of the results to winds in the North Atlantic. Their set-up will be described in details in section 4.3. All the runs presented below were integrated starting from the Levitus (1982) temperatures and salinities, with velocities, atmospheric temperature and specific humidity set to zero, and without initial sea ice coverage. They were run for more than 2000 years without flux adjustments.

3 Sensitivity of the AMOC to vertical diffusivity

Fig. 2 (top) shows the mean meridional streamfunction in the standard version of the model with a background vertical diffusivity $\kappa = 0.1 \text{ cm}^2 \cdot \text{s}^{-1}$. This value is smaller than generally used in coupled models of similar resolution. It corresponds to estimates in the ocean interior based on observations of turbulence (Gregg 1989), tracer release experi-
ments (Ledwell et al. 1993) and internal wave processes (Toole et al. 1994). The zonally integrated streamfunction is in good qualitative agreement with observations (Talley et al. 2003, Ganachaud and Wunsch 2000), in spite of a rather weak maximum value: about 12 Sv of warm water flow northward in the upper ocean, sink in the Nordic and Irminger Seas and return southward at depth (below about 700 m) as North Atlantic Deep Water (NADW). Given the coarse resolution of the model, the amount of overflow of dense water masses over the ridges between Greenland and Scotland is rather well represented (Dickson and Brown, 1994). Note that there is no deep water formation in the Labrador Sea because of its narrowness, as detailed in Montoya et al. (2005). The NADW cell reaches a depth of roughly 2300m, that is rather shallow as compared to observations, and the 4 Sv inflow of Antarctic Bottom Water (AABW) at the bottom of the Atlantic is on the contrary relatively thick (Talley et al. 2003).

Both the shape (Fig. 2) and magnitude (Fig. 4) of the AMOC are sensitive to the background value of vertical diffusivity $\kappa$. Fig. 2 shows that the broad upwelling in the Atlantic interior increases with $\kappa$, consistently with a vertical advection-diffusion balance. This increased upwelling also appears clearly on Fig. 3 showing the meridional overturning computed in $\sigma_0$-coordinates and thus highlighting the water mass transformations and intensified mixing in the Atlantic interior. The overflow over the Greenland-Scotland ridge first increases with $\kappa$, as well as the depth of the NADW (compare Fig. 2 top and
middle panels), while at high vertical diffusivities, the overflow vanishes and the depth reached by NADW decreases again (Fig. 2, bottom). The maximum density of the water mass formed in the high latitudes as shown in Fig. 3 exhibits a similar dependency at high vertical diffusivities. Deep convection then primarily takes place in the Irminger Sea, south of the ridges, rather than in the Nordic Seas. In Fig. 4, we plot the maximum $M_{max}$ of the streamfunction computed in depth coordinate in the domain $[25^\circ N-70^\circ N, 500m-5000m]$. It is reached between 600 and 1000 m depth and between $37^\circ N$ and $45^\circ N$ in all the runs. $M_{max}$ generally increases with vertical diffusivity, in agreement with numerous previous modelling studies (e.g. Bryan 1987, Colin de Verdière 1988, Marotzke 1997). Exceptions are the runs using $\kappa=0.5$ cm$^2$/s and $\kappa=0.75$ cm$^2$/s, which play a special role due to changes in deep convection sites, as will be explained below. For vertical diffusivity less than $\kappa=0.5$ cm$^2$/s, the increase appears to be linear, and a change of regime seems to occur for $\kappa \geq 0.5$ cm$^2$/s. Very similar results are obtained with the density-space streamfunction.

In order to compare with previous studies, we give here the least square fit of the curve in Fig. 4 with a power law. The coefficient $\alpha = 0.17$ is much weaker than the $2/3$ suggested by simple scaling arguments in a one hemispheric configuration. It is increased to $\alpha = 0.35$ when fitting the maximum of the overturning in density-coordinates (see Park and Bryan 2000 and Klinger et al. 2003 for a discussion), which is still weaker than the
scaling prediction. That is because several additional processes that are not considered to derive Eq. (1) can have an effect in a global coupled model. In particular, in a one hemispheric configuration, the water masses that sink at high latitudes necessarily upwell in the Atlantic basin. This differs from the real ocean and a global model, in which part of the flow can be exported towards the Southern Ocean at 30°S. In order to discuss the effect of diffusion, it is thus helpful to distinguish the large scale upwelling $W_{\text{Atl}}$ (in Sv) taking place in the Atlantic basin between the latitude of maximum overturning and 30°S from the total maximum overturning $M_{\text{max}}$. We define

$$W_{\text{Atl}} = M_{\text{max}} - M_S,$$

where $M_S$ is the outflow of water into the Southern Ocean at 30°S. The latter can be determined directly as the maximum value of the meridional streamfunction at 30°S. The ratio $R = M_S/M_{\text{max}}$ gives a measure for the interhemispheric transport efficiency of the Atlantic overturning. If it equals zero, there is no southern outflow of NADW and the overturning is limited to the Atlantic basin. If $R=1$, the total amount of water downwelling in the northern North Atlantic is exported to the Southern Ocean. Recent computations from Talley et al. (2003) suggest that $R = 78 \pm 10\%$ in the real ocean while values inferred from state-of-the-art coupled GCMs that are tuned to represent present climate as realistically as possible are subject to larger uncertainty (Table 1). Understanding the
sensitivity of large scale quantities such as $R$ or $M_{\text{max}}$ is of primary importance both for
the full comprehension of the role of the ocean in climate and for the evaluation of climate
models. Due to computational costs, however, state-of-the-art GCMs cannot afford the
numerous experiments that it requires. This can be done in coupled model of intermediate
complexity as CLIMBER-3α. In the following, we examine successively the sensitivity of
$M_S$ and $W_{\text{Atl}}$ to the background vertical diffusivity $\kappa$. We aim at decomposing the AMOC
into distinct components which correspond to different physical processes with different
sensitivity to vertical mixing.

4 A Decomposition of the AMOC

4.1 Outflow at 30°S and deep convection

Fig. 5 (upper panel) shows that the part of the NADW flow that is exported towards
the Southern Ocean at 30°S, $M_S$, is only weakly sensitive to the background vertical
diffusivity. It varies by less than 2 Sv for $\kappa$ ranging from 0.05 to 1.0 $cm^2 \cdot s^{-1}$. It increases
linearly but very slowly with increasing values up to $\kappa = 0.4$ $cm^2 \cdot s^{-1}$, is weak for $\kappa = 0.5$
$cm^2 \cdot s^{-1}$, recovers a higher value for $\kappa = 0.6$ $cm^2 \cdot s^{-1}$, and then decreases again for higher
coefficients. This variation is robust to the use of density-coordinates and correlates very
well with the intensity of deep convection in the Nordic Seas. The sensitivity of the latter
to vertical diffusivity has already been observed in Fig. 2. For $\kappa \leq 0.4$ $cm^2 \cdot s^{-1}$ as
well as for $\kappa=0.6 \text{ cm}^2 \cdot \text{s}^{-1}$, deep convection takes place primarily in the Nordic Seas, inducing the circulation cell north of the Greenland-Scotland ridge visible in Fig. 2 (top and middle panels). For $\kappa=0.5 \text{ cm}^2 \cdot \text{s}^{-1}$ and $\kappa \geq 0.75 \text{ cm}^2 \cdot \text{s}^{-1}$, on the other hand, deep mixing takes place exclusively in the Irminger Sea, i.e. south of the ridges, and the circulation north of the latter vanishes (Fig. 2 bottom). Fig. 5 (upper panel) shows that the intensity of the vertical circulation cell north of the Greenland-Scotland ridge, eventually entering the Atlantic basin through the overflow, correlates very well with the amount of NADW exported towards the Southern Ocean. The shift of deep convection location with increasing $\kappa$ is primarily due to two combined effects. First, intense mixing in the high latitudes, in particular in the Irminger Sea, tends to homogenise the water column locally, favoring deep convection. Second, increased vertical diffusivities lead to an increased mixing in the Atlantic interior and thus to a stronger decrease of the vertical density difference between upper and lower water masses along the path to the convection sites. This favors deep convection earlier along this path. Note that in both cases, deep convection is then preferably shifted to the Irminger Sea since it is also an area of intense cooling and dooming, thus preconditioned for deep convection. Relatively deep mixing is occurring in this area even in the standard run using $\kappa=0.1 \text{ cm}^2 \cdot \text{s}^{-1}$, as shown in Montoya et al. 2005. These two effects can be illustrated through the analysis of additional simulations where high values of mixing are imposed equatorward of 40°.
latitude only, with $\kappa$ fixed to a low value of $\kappa=0.1 \, \text{cm}^2 \cdot \text{s}^{-1}$ at higher latitudes. $M_S$ and the magnitude of the overflow are almost identical in the runs $\kappa_{\text{lowlat}}=0.3 \, \text{cm}^2 \cdot \text{s}^{-1}$ and $\kappa=0.3 \, \text{cm}^2 \cdot \text{s}^{-1}$, while deep convection north of the ridges is re-established for $\kappa_{\text{lowlat}}=0.5 \, \text{cm}^2 \cdot \text{s}^{-1}$ and $\kappa_{\text{lowlat}}=0.75 \, \text{cm}^2 \cdot \text{s}^{-1}$ as compared to the standard runs, and it is enhanced for $\kappa_{\text{lowlat}}=0.6 \, \text{cm}^2 \cdot \text{s}^{-1}$ (Fig. 5, upper panel, dashed lines). Overflow above the northern ridges and outflow at $30^\circ\text{S}$ are then both increased. The situation changes for $\kappa_{\text{lowlat}} \geq 1.0 \, \text{cm}^2 \cdot \text{s}^{-1}$ where overflow and outflow decrease again because of the second effect described above. Note that the transition is not sharp. During spin-up, the run using $\kappa=0.6 \, \text{cm}^2 \cdot \text{s}^{-1}$ exhibits intermittent shifts between the two sinking regions before steady state is established with a significant amount of deep water formed in the Nordic Seas (not shown). The transition thus occurs in the interval $\kappa \in [0.5 - 0.6 \, \text{cm}^2 \cdot \text{s}^{-1}]$, suggesting that other effects such as atmospheric feedbacks play a role.

To further document the link between the location of deep convection at high latitudes and the outflow at $30^\circ\text{S}$, we plot in Fig. 5 (lower panel) the maximal depth reached by the NADW at the latitude of maximum overturning and at $30^\circ\text{S}$. At each of these two latitudes, the depth is diagnosed where the meridional streamfunction is zero. In the standard runs, it is strongly correlated with the deep convection location, showing that when deep convection takes place in the Nordic Seas, NADW is denser, reaches higher depths and a larger fraction is exported southward. This correlation still holds at the
latitude of maximum overturning in the runs using $\kappa^{\text{lowlat}}$. At 30°S, however, this depth saturates for $\kappa^{\text{lowlat}} = 0.5 \text{ cm}^2 \cdot \text{s}^{-1}$, and decreases again when further increasing $\kappa^{\text{lowlat}}$, as a result of intense mixing in the Atlantic interior. We investigate this component in details in the next section.

It is beyond the scope of this paper to analyse the fate of the NADW exported at 30°S. Upwelling in the Southern Ocean as a result of wind forcing in the Drake Passage (Toggweiler and Samuels 1995) and mixing with the Circumpolar Deep Water around Antarctica to finally upwell in the Indo-Pacific under the action of mixing are possible processes that would need to be investigated in a separate study. Hints can however be found in the analysis of the ratio $R = M_S/M_{\text{max}}$ introduced above. In CLIMBER-3α, $R$ decreases linearly with increasing vertical diffusivity (Fig. 6) and is almost unaffected by restricting the increase of background vertical diffusivity to low latitudes ($\kappa^{\text{lowlat}}$, Fig. 6). $M_{\text{max}}$ thus increases faster than $M_S$ with increasing $\kappa$. This suggests that vertical diffusion is most effective in controlling the strength of the overturning in the Atlantic mid-latitudes and Tropics and allows us to speculate that mixing in the Indo-Pacific probably plays a minor role. The decrease of the efficiency ratio $R$ with $\kappa$ differs from Prange et al. (2003) who find that $R$ is constant around 0.75 in their three-dimensional forced global ocean GCM with changing vertical diffusivities. The values obtained in CLIMBER-3α are in the range of other GCMs for $\kappa \leq 0.4 \text{ cm}^2 \cdot \text{s}^{-1}$ and become lower for
larger $\kappa$ (compare Table 1). This suggests that realistic values of $\kappa$ are in this interval.

For $\kappa \geq 0.75 \text{ cm}^2 \cdot \text{s}^{-1}$, $R \leq 50\%$, i.e. more than half of NADW upwells in the Atlantic.

## 4.2 Advection-diffusion balance

We investigate now the sensitivity of the Atlantic upwelling $W_{\text{Atl}}$ to the background vertical diffusivity (Fig. 7). By definition $W_{\text{Atl}}$ corresponds to the total upwelling $W_w$ taking place in the Atlantic calculated by $W_w = \int \int_D w \, dx \, dy$ where $w$ is the vertical velocity given by the model and $D$ is the Atlantic oceanic domain extending from 30°S to the latitude of the maximum of the overturning, around 40°N. $W_w$ is still a function of depth. We define the level of no horizontal motion as the depth at which $W_w = W_{\text{Atl}}$ and all following diagnostics will be shown at this level. It lies between 600 and 1000 m in all the experiments, which corresponds well to the level of maximum overturning in the North Atlantic.

The fit of $W_{\text{Atl}}$ by a power law $W = W_1 \cdot (\kappa/\kappa_0)^\alpha$ yields a coefficient $\alpha=0.59$. This value is quite close to the $2/3$ power law of Eq. (1). However, it implies that the Atlantic upwelling reaches zero for no vertical diffusivity, which does not seem to be the case in Fig. 7. The fit with a constant offset $W = W_1 \cdot (\kappa/\kappa_0)^\alpha + W_0$, as shown in Fig. 7, rather suggests a linear increase of $W_{\text{Atl}}$ with $\kappa$, with a slope of $7.3 \text{ Sv}$. This linearity is consistent with Toggweiler and Samuels’ (1998) findings using an earlier global version of MOM, although they obtained a much stronger slope (of about $23 \text{ Sv cm}^{-2} \cdot \text{s}$). We speculate that the
difference results from their use of restoring boundary conditions, which allows for strong
coupling between the circulation and freshwater fluxes and therefore a stronger effect of
mixing from the surface to the deep ocean. A constant offset of $W_0=2.5$ Sv is found in the
limit of zero background vertical diffusivity, assuming that the linearity holds down to this
limit. Very similar results are again obtained with the density-coordinate streamfunction
(not shown).

The scaling law of Eq. (1) was based on the assumption of a balance between the
upwelling of dense waters and vertical diffusion at the base of the thermocline. Locally,
this balance can be written as:

$$w_{AD}(x, y, z) \partial_z \rho(x, y, z) = \partial_z (\kappa^*(x, y, z) \partial_z \rho(x, y, z)) \quad (3)$$

where $w_{AD}$ is the vertical advection velocity induced by diffusion of waters with the density
$\rho$. $\kappa^*$ is the local vertical diffusivity in the model. It is a function of the three dimensions
$x, y$ and $z$ because of the parametrisations of enhanced mixing over topography and KPP
(see sec. 2). Note that the applicability of Eq. (3) is not trivial. Especially, as pointed out
by Munk and Wunsch (1998), it is based on the strong assumption that vertical diffusion
of temperature and salinity are indeed both balanced by the same advection. It therefore
also assumes a linear equation of state. We will show however that it is justified for the
large scale upwelling within the entire basin. $w_{AD}$ is plotted in Fig. 8 for the run using
\( \kappa = 0.4 \text{ cm}^2 \cdot \text{s}^{-1} \) together with the vertical velocity \( w \) given by the model, at the level of no motion. \( w \) is diagnosed by the continuity equation and is therefore very noisy. In Fig. 8, it has been smoothed by averaging each grid cell with the nearest points but remains noisy. \( w_{AD} \) results from the density field and is therefore much smoother. Both fields clearly show a large scale upwelling in the interior of the Atlantic, strongest along the subtropical gyre circulation and along the path of incoming waters in the southern hemisphere, where vertical density gradients are largest. Fig. 9 compares the integrated upwelling computed from \( w \) and from \( w_{AD} \) in the Atlantic interior, that is without taking the grid points adjacent to the coast into account, for the different runs. The very good agreement suggests that the one-dimensional balance (3) is indeed a good approximation of the large scale upwelling taking place in the ocean interior in the model. At the basin boundaries, and especially along the western boundary, a strong upwelling is revealed by \( w \) but is not captured by \( w_{AD} \) (Fig. 8). Additional processes that will be discussed below significantly contribute to the upwelling there.

In order to quantify the total contribution of the upwelling induced by the background diffusivity only to the total Atlantic upwelling, we now compute the integral

\[
W_{AD} = \kappa \int \int_{D} \frac{\partial^2 \rho}{\partial z \partial \rho} dxdy
\]
over the whole domain $D$. In the interior of the basin, this is justified by the fact that the difference between $\kappa^*$ and $\kappa$ is weak (Fig. 1). The effect of $\kappa^*$ at the boundaries will be quantified below. $W_{AD}$ is shown in Fig. 10. It increases linearly with $\kappa$ and extrapolates to the origin. The linearity differs from immediate results of the scaling law (1) which is based, as all the classic scaling laws for the meridional overturning (Bryan 1987, Gnanadesikan 1999, Park 1999, Park and Bryan 2000...), on the geostrophic thermal wind balance which, together with the continuity condition, yields

$$W_{AD} = \frac{g \Delta \rho D^2}{\rho_0 \epsilon}.$$  \hspace{1cm} (5)

$g$ is the gravity constant, $\rho_0$ a reference density, $D$ the pycnocline depth and $\epsilon$ a geometry factor. The assumption that is usually made is that both $\epsilon$ and $\Delta \rho$ are constant, and variations of $W_{AD}$ are analysed with regards to variations of $D$. This differs from our model results where the pycnocline depth $D$ is practically constant (Fig. 11, left), while the meridional density gradient $\Delta \rho$ increases linearly with $\kappa$ up to $\kappa=1$ cm$^2$ s$^{-1}$ (Fig. 11, right). Note that $\Delta \rho$ is here considered at the grid point closest to the level of no motion and the pycnocline depth (Fig. 11, left) in the different runs, that is 680 m, but the linearity is very robust and verified at any vertical levels (see Griesel and Maqueda 2005 for further details). Taking the variation of $\Delta \rho$ with $\kappa$ into account, the scaling (1)
can be reduced to

\[ \Psi \sim \kappa^{2/3} \Delta \rho^{1/3} \sim \kappa^{2/3} \kappa^{1/3} = \kappa, \]

in agreement with the linearity found in Fig. 10. (For the run using \( \kappa = 1.5 \text{ cm}^2 \cdot \text{s}^{-1} \), the mixing is too strong to sustain a tracer distribution comparable to observations.) The fact that the pycnocline depth \( D \) is independent of \( \kappa \) (Fig. 11, left) is also consistent with the scaling \( D \sim (\kappa/\Delta \rho)^{1/3} \) implied by Eq. (1) (e.g. Park and Bryan 2000) when accounting for the linear relation between \( \Delta \rho \) and \( \kappa \).

Our findings are thus consistent with the previous scalings, but they point out that the meridional density difference may not be assumed constant in coupled simulations. Most of the studies previously dedicated to the verification of scaling laws have been carried out using forced oceanic GCMs, where the restoring surface boundary conditions might prevent the meridional density gradient \( \Delta \rho \) to vary significantly. The ocean is thus only free to adjust through varying its pycnocline depth. On the contrary, in our coupled simulations where only the winds are kept constant, \( \Delta \rho \) varies significantly while the pycnocline depth is constant. This result is thus consistent with theories of the “ventilated thermocline” which suggest that the pycnocline depth is primarily determined by the winds (e.g. Luyten et al. 1983), in particular in the case of weak diapycnal diffusivity (Boccaletti et al. 2004). Additional experiments presented below suggest however that winds in the Southern Ocean might be playing the dominant role. Note finally that the
shifts in deep convection location discussed above are not be detected in $W_{AD}$ (Fig. 10) as they were in $M_S$ (Fig. 5) indicating that they do not lead to significant variations in the geometric coefficient $\epsilon$. The scaling (5) is indeed valid in the region where the southward flow of NADW is a western boundary current (WBC), which is justified merely south of 50°N in the model, whatever deep water formation site is favored. $\epsilon$ can thus be assumed constant as in classic scalings.

In Eq. (4), the variations of $\kappa$ are not taken into account. The contribution $W_{ADtopog}$ to the upwelling due to enhanced mixing above the topography, that is essentially along the boundaries at this depth, is estimated by

$$W_{ADtopog} = \int \int_{\delta D} \frac{\partial_z [(\kappa^* - \kappa) \partial_z \rho]}{\partial_z \rho} dx dy = \int \int_{\delta D} (\kappa^* - \kappa) \frac{\partial^2 \rho}{\partial_z \rho} dx dy + \int \int_{\delta D} \partial_z \kappa^* dx dy. \quad (7)$$

The integral is here only taken over grid points $\delta D$ of $D$ adjacent to the coast. $W_{ADtopog}$ scatters between -0.5 Sv and 1 Sv with no clear trend with $\kappa$ (Fig. 10). The negative contribution comes from the second term on the right hand side in Eq. (7), as $\kappa^*$ increases with depth. This competes the first term on the right hand side, accounting for enhanced mixing over topography. The weakness of $W_{ADtopog}$ is consistent with findings of Hasumi and Suginohara (1999), whose simulations show that upwelling and circulation of the deep water masses is affected by localized deep mixing but that $M_{max}$ is insensitive to this parametrisation, and with more recent modelling results from Saenko and Merryfield.
The sum $W_{AD} + W_{ADtopog}$ is still weaker than $W_{Atl}$, indicating that not all of the upwelling $W_{Atl}$ in the Atlantic can be explained by a balance between vertical advection and diffusion. Horizontal terms in the dynamic equation of $\rho$ can for example be locally important, especially along the boundaries where the isopycnals are tilted. Böning et al. (1995) pointed at the upwelling in the WBC as primarily responsible for the weak poleward heat transport in the Atlantic in coarse resolution models, as it provides a short-cut for a substantial amount of NADW to upwell in the Atlantic and thus reduces the efficiency $R$ of the overturning. Veronis (1975) proposed that the upwelling of cold water along the WBC is necessary to balance the spurious cross-isopycnal fluxes due to horizontal diffusion across steeply sloping isopycnals in the WBC. This so-called “Veronis effect” should be weak in our model as no horizontal diffusion is imposed and numerical diffusion has been drastically reduced by the use of the low-diffusive tracer advection scheme. However, Huck et al. (1999) and Yang (2003) demonstrated that upwelling along the boundaries can also be linked to the lateral boundary layer dynamics in coarse-resolution models, and not only to the thermodynamic “Veronis” effect. The upwelling along the boundaries that is not due to the vertical advection-diffusion balance can be computed as

$$W_{bound} = \int \int_{\delta D} w dxdy - \int \int_{\delta D} \frac{\partial_z (\kappa^* \frac{\partial_z \rho}{\partial \rho})}{\partial \rho} dxdy,$$

(8)
The second term on the right hand side of Eq. (8) is the upwelling balancing the total vertical diffusion taking place along the boundaries. We show $W_{\text{bound}}$ in Fig. 10 at the same depth as the advection-diffusion upwelling $W_{AD}$. $W_{\text{bound}}$ is between 2 and 4 Sv and increases weakly with $\kappa$. The sum $W_{AD} + W_{AD\text{topog}} + W_{\text{bound}}$ is also plotted in Fig. 10. Its very good agreement with the total Atlantic upwelling $W_{Atl}$ justifies a posteriori the decomposition that we present in this study and illustrates that away from the boundaries, advection-diffusion balance holds. Note that it is not a trivial decomposition since only one of the three terms, $W_{\text{bound}}$, is computed directly from the velocity field, and only along the coast. The other two result from the density field in combination with the strong assumption of a vertical advection-diffusion balance. The first term $W_{AD}$ is dominant and balances the background constant diffusion. It increases in first order linearly with the vertical diffusion coefficient and thereby dominates the shape of $W_{Atl}$ as a function of $\kappa$. $W_{AD\text{topog}}$ is very weak and can account either for an upwelling or a downwelling. It has no significant trend with $\kappa$. The residual term $W_{\text{bound}}$ is computed along the boundaries only. It depends weakly on $\kappa$. Its sensitivity to the wind forcing is discussed in the next section.

4.3 Wind-dependent upwelling along the boundaries

It can be shown that $W_{\text{bound}}$ occurs primarily in the west between 20°N and 40°N. Yang (2003) suggested that upwelling at the western boundary in coarse resolution models is
directly linked to the effect of the wind stress curl on a poorly resolved western boundary layer (WBL). The latter is required not only to balance the interior Sverdrup transport to close the gyre circulation, but also to dissipate the vorticity imposed by the wind-stress curl. If it is not resolved, strong spurious upwelling and downwelling develop in order to dissipate the wind-imposed vorticity by distorting some important dynamics. The width $\delta$ of the WBL is given by $\delta \approx (A_H/\beta)^{1/3}$ (Munk 1950), where $\beta$ is the meridional derivative of the Coriolis parameter and $A_H$ the lateral viscosity. In the model, $A_H = 3.2 \cdot 10^5 m^2 \cdot s^{-1}$ so that $\delta \approx 250 km$ at 30°N, while the zonal resolution at this latitude is of the order of 360 km. The WBL is thus poorly resolved and the effect described by Yang (2003) could be at play. In addition, as the wind stress is the same in all our experiments described so far (prescribed to NCEP), this would explain the approximately constant contribution of this upwelling for different values of $\kappa$. To further investigate this mechanism, we set additional sensitivity experiments for the runs with $\kappa=0.1, 0.4$ and 1 $cm^2 \cdot s^{-1}$. For each of them, the zonal component $\tau_x$ of the wind stress was either reduced or increased in the latitude band between 5°N and 55°N according to the sinusoidal distribution: $\tau_x = \tau_{x0} \cdot (1 + (c_\tau - 1) \cdot \sin(\pi \cdot (y - 5)/50)$, where $y$ represents the latitude in degrees and $c_\tau$ the wind amplification factor successively set to $c_\tau = 0.5, 1$ (standard runs) and 1.5. The sinusoidal distribution avoids artificial divergence at the northern and southern limits of the modified area and is maximum in the region of the main boundary upwelling between
20ºN and 40ºN. As seen in Fig. 12, both the Atlantic upwelling \( W_{\text{Atl}} = M_{\text{max}} - M_S \) and the upwelling along boundaries \( W_{\text{bound}} \) increase linearly with the wind amplification factor, while both components due to advection-diffusion balance are constant. This confirms that the residual upwelling along the boundaries is dependent on wind forcing. Although its sensitivity seems to decrease with \( \kappa \), this result would be consistent with the suggestion of Yang (2003). Note that Rahmstorf (1995) also finds that the ageostrophic, frictional component dominates the boundary vertical flow in his coarse resolution model.

Further analysis of the simulations reveals that the pycnocline depth is also very weakly sensitive to changes in the wind strength in the northern Atlantic subtropics (not shown). Following the discussion of section 4.2, this suggests that winds in the Southern Ocean rather than in the low latitudes might have the dominant effect on the density structure in the Atlantic. This is consistent with Gnanadesikan (1999) and with several other studies proposing that Southern Ocean winds play a major role in controlling the Atlantic overturning magnitude (e.g. Mc Dermott 1996, Klinger et al. 2003).

5 Conclusions and discussion

The sensitivity of the AMOC to vertical diffusivity was investigated in a global coupled model and used to decompose the strength of the Atlantic overturning \( M_{\text{max}} \) into simple components. The aim was to extract the main physical processes composing \( M_{\text{max}} \) in
the coupled model and to discuss their sensitivity to $\kappa$. Note that we neglected the interaction between AABW and NADW although the coupling between the two, especially through topography-enhanced mixing, might potentially be important (Kamenkovich and Goodman 2000, Levermann and Mignot 2005). The set-up of the ocean component of the model allowed vertical diffusivities in the ocean interior as low as $\kappa=0.05 \text{ cm}^2 \cdot \text{s}^{-1}$, and this value was increased up to $\kappa=1.5 \text{ cm}^2 \cdot \text{s}^{-1}$ in a set of simulations. Our decomposition can be summarized as follows:

$$M_{\text{max}} = W_{\text{Atl}} + M_S \quad \text{with}$$

$$W_{\text{Atl}} = W_{\text{AD}} + W_{\text{ADtopog}} + W_{\text{bound}}$$

The term $W_{\text{AD}}$ represents the broad upwelling balancing the vertical diffusion in the Atlantic basin. It was computed by assuming a local one-dimensional balance between vertical advection and diffusion. Although its application is not trivial (see discussion by Munk and Wunsch 1998), a similar assumption was used by Munk (1966) to deduce one of the first global estimate of the amount of oceanic mixing and was since then widely used, especially by the geochemical community. Furthermore, it appears as the vertical balance in one class of solutions to the so-called thermocline equations (Stommel and Webster 1962) and it constitutes the starting point of several thermohaline theories (e.g. Bryan and Cox 1967, Bryan 1987, Gnanadesikan 1999). The resulting large-scale volume
flux \( W_{AD} \) is to first approximation proportional to \( \kappa \), and is responsible for the linear dependance of \( W_{Atl} \) on \( \kappa \). This linearity is in contradiction with the implicit assumptions of previous scaling arguments. Nevertheless, we showed that the latter could be reconciled with our model results by incorporating the linear increase of the density difference between high and low latitudes with \( \kappa \). We argue that variations of the latter are particularly important here because of the coupling with the atmosphere as opposed to previous studies that used forced ocean GCMs where the meridional density gradient was largely constrained by the surface restoring conditions. On the other hand, the pycnocline depth is approximately constant in our experiments, while it is classically varying with the AMOC strength in forced simulations. The weak sensitivity of the pycnocline depth has already been reported by Levermann and Griesel (2004) in another set of experiments, and it is consistent with results from another coupled model of intermediate complexity (Gnanadesikan, pers. comm., 2005). Our results suggest that winds in the Southern Ocean primarily set the pycnocline depth and this issue should be further investigated in future studies.

\( W_{ADtopog} \) is the upwelling resulting from topographically enhanced mixing along the Atlantic coast. This term can be positive or negative as a result of an increasing value of \( \kappa \) with depth. Its order of magnitude is weaker than 1 Sv. The upwelling term \( W_{bound} \) is computed from the vertical velocity given by the model along the Atlantic coast only.
It varies weakly with \( \kappa \) and is strongest along the western boundary. We showed that \( W_{\text{bound}} \) is linearly dependent on the wind stress in the North Atlantic, consistent with the study of Yang (2003).

The dominant term in Eq. (10), \( W_{AD} \), is computed merely from the tracer distribution, while \( W_{\text{bound}} \) derives from the velocity field at the boundary only. The fact that the sum of these two close the budget of upwelling in the Atlantic basin allows us to interpret the two-dimensional \( w_{AD} \)-field of Fig. 8 as a smoothed field of the upwelling velocities (computed through the continuity equation) in the ocean interior that has the same integral over the Atlantic excluding the boundary effect \( W_{\text{bound}} \). This conclusion is of prior importance for the geochemical community who widely uses it to infer dynamical statements on observed passive tracers and for observational estimates of mixing coefficients (e.g. Naveira-Garabato, pers. comm., 2005).

The export of NADW at 30°N, \( M_S \), varies rather weakly with \( \kappa \). It is strongly correlated with the strength of the overflow over the Greenland-Scotland ridge, and thus with the location of deep convection in the North Atlantic high latitudes, that was shown to be sensitive to \( \kappa \) as well. It follows that \( M_{\text{max}} \) is sensitive to the characteristics of the water mass formed at a few grid points in the high latitudes, as already shown in other modelling studies (e.g. Lenderik and Haarsma 1994, Rahmstorf 1995). However, in our model, this link is primarily felt by the amount of NADW exported at 30°S, while processes in the
Atlantic are not strongly influenced. This is consistent with results from Brix and Gerdes (2003)’s global forced model who also show a close relationship between enhanced southward export of NADW at $30^\circ S$ and deep convection north of the Greenland-Scotland ridge.

The efficiency $R = M_S/M_{max}$, on the other hand, was found to decrease linearly with $\kappa$ and to be largely independent of deep convection location. This could indicate that $M_{max}$ is more strongly controlled by vertical mixing in the Atlantic than by that in the Indo-Pacific basin, although this issue was not investigated in details here. It also showed that small values of $\kappa$, namely $\kappa \leq 0.4 \text{ cm}^2 \cdot \text{s}^{-1}$, are required to obtain values of $R$ similar to that inferred from observations or from higher resolution GCMs. Note that the sensitivity of this ratio $R$ is difficult to obtain in these computationally expensive models.

The variations of $M_{max}$ with $\kappa$ result from the combined variations of all the terms of the decomposition. Our analysis suggests that in general, scalings of $M_{max}$ with $\kappa$ should take a constant offset into account, and that scalings such as that presented in Fig. 4 are not physical. This offset should be of the order of 10-11 Sv, where 8-9 Sv come from the southern outflow (Fig. 5) and 2 Sv from the offset of $W_{Atl}$ (Fig. 7). The approximately constant value of the Southern Ocean export is probably at least partly set by the winds in the Southern Ocean, as suggested e.g. by Rahmstorf and England (1997). The offset associated to $W_{Atl}$ is linked to the term $W_{\text{bound}}$ in our decomposition. Yet, its physical
origin is more difficult to infer since the dynamics and circulation within the Atlantic might significantly change in the limit of zero vertical diffusivity. For comparison, the fit of $M_{\text{max}}$ with an offset of 10.5 Sv yields an exponent of $\alpha=0.57$ in the standard runs (Fig. 13) and $\alpha=0.73$ in the runs using $\kappa_{\text{lowlat}}$ (not shown). These exponents result however from the combination of different components with different sensitivity to $\kappa$. The validity of scaling laws in general is indeed related to unchanged physical processes. Because of the switch in deep convection location, this condition is not fulfilled in both sets of experiments. In the range of background diffusivity values where no switch in deep convection sites is detected, that is for $\kappa_{\text{lowlat}} < 1 \text{ cm}^2 \cdot \text{s}^{-1}$, $M_{\text{max}}$ scales linearly with $\kappa_{\text{lowlat}}$ (Fig. 13, dashed line), in agreement with the decomposition. The offset value of 10.7 Sv is very close to our prediction. To conclude, we first recall that scaling laws should in general be derived from dynamics and physical laws and not be simply fitted. Furthermore, we suggest that scaling laws be interpreted with much care not only due to the generally very small range of $\kappa$ (that is physically justified) but also due to shifts in important physical processes such as deep convection location.

**Acknowledgments** The authors would like to acknowledge the efforts and achievements of Marisa Montoya, Matthias Hofmann and Miguel Morales Maqueda in developing the
model. They are also grateful to Andrey Ganopolski and Stefan Rahmstorf for useful discussions and to Anand Gnanadesikan and an anonymous reviewer for constructive comments that helped us to greatly clarify the results. J.M. would also like to thank Jerome Sirven for stimulating discussions. J.M. and A.L. were supported by the Gary Comer foundation. A.G. was funded through the James S. McDonnell Foundation Centennial Fellowship.
